

# Commodity Booms and Structural Transformation: The Role of Input Use and Land Inequality <sup>\*</sup>

Andrei Arminio Laskievic <sup>†</sup>

São Paulo School of Economics-FGV

June 2021

## Abstract

This paper studies the effects of an agricultural commodity price boom on structural transformation. I construct a shift-share measure of exposure to the commodity shock by combining climate- and soil-induced variation in agricultural production patterns among municipalities in Brazil with fluctuations in international commodity prices between 2000 and 2010. I show that labor was reallocated away from agriculture towards the manufacturing sector in locations more exposed to the commodities boom. Using data from the Population and Agricultural Censuses, I argue that the results are consistent with greater use of capital inputs in agriculture, which worked as substitutes for farm labor, and greater land inequality in more exposed locations, which ultimately displaced workers from the agricultural sector.

**Keywords:** Commodity Booms, Structural Transformation, Input Use in Agriculture, Land Inequality

# 1 Introduction

The relationship between agriculture and economic development has been a long-studied subject in the growth literature (Engerman and Sokoloff, 1994; Vollrath, 2011). Whether the expansion of the agricultural sector promotes or curbs structural transformation is a fundamental and highly debated question (Lewis, 1954; Rostow, 1960; Gollin et al., 2002). In particular, open economies can experience both an increase or decrease in industrialization depending on the comparative advantage of the agricultural sector and its export composition (Matsuyama, 1992). The classical theoretical models have focused on productivity changes, both in agriculture and manufacturing, as the main driver of structural change but have missed some important microeconomic mechanisms related to trade shocks and agricultural modernization that can be at play in developing economies in which agriculture is the sector with the comparative advantage (Alessandria et al., 2021).

Recently, a growing empirical literature have studied how shocks to agricultural productivity affect structural transformation in local economies. The evidence regarding the direction of structural change is, however, still scarce and ambiguous (Bustos et al., 2016; Gollin et al., 2018; Moscona, 2018; Uribe-Castro, 2019). Such studies also tend to focus on particular crops and might miss the general effects that impact the agricultural sector more generally. Isolating the forces that can operate the relationship between the expansion of the agricultural sector and structural transformation in open economies is a fundamental challenge in the literature and is, ultimately, an empirical question.

In this paper, I explore the 2000s commodities boom as an exogenous economic shock and analyze how the underlying structure of the agricultural sector in Brazil changed after the sharp rise in the prices of a large basket of internationally traded commodities. In particular, I look at the change in employment shares across sectors and argue that differential input use (labor, capital, and land) worked as a key mechanism in driving the effects. Additionally, I explore inequality in landholdings as another important mechanism in generating structural change. Land inequality is often overlooked in the structural transformation literature and can be important in accounting for both changes in agricultural productivity and the displacement of workers.

To empirically assess the effect of the commodity boom on local development and structural change, I propose a shift-share measure to isolate municipalities that were more exposed to the shock. I construct the exposure shares by using actual observed crop yields across Brazilian municipalities and data on crop potential yields from the Food and Agriculture Organization (FAO)’s Global Agro-Ecological Zones (GAEZ) project. I combine both variables into a fractional multinomial logit (FML) model of crop choice proposed by Fiszbein

(2019), which calculates predicted shares for the crops in my sample for each municipality. I then interact the predicted shares with the exogenous variation in international prices of commodities between 2000 and 2010, which represents my shift (or shock) variable.

I first explore the effect of the commodity boom on employment shares and find that regions that were more exposed to the commodity boom experienced a reallocation of labor away from agriculture and towards the manufacturing sector. My estimates imply that the commodity price boom explains 10% of the observed differences in the reduction of the agricultural share across Brazilian municipalities and 18% of the corresponding differences in the growth of the manufacturing employment share. I also do not observe any effect of the commodities shock on employment share in services at the local level. Using matched employer-employee data on all formal jobs in Brazil, I further show that the reallocation effect was the same between formal and informal jobs. Moreover, the increase in industrial employment was widespread across the whole manufacturing sector and did not benefit any specific industry.

Next, I explore potential mechanisms related to agricultural modernization that led to the observed reallocation of workers. First, I study how the intensity in inputs use changed in more affected regions. I observe an increase in the use of capital, measured by the use of machines and genetically engineered seeds in the farms. I argue that the higher use of capital in the farms worked as substitutes to agricultural workers. I then explore how the change in land inequality after the shock might have contributed to the displacement of agricultural workers. I find that land inequality increased in more exposed municipalities by looking at the Land Gini and the number and area of the largest farms inside the regions. The share of land used in agriculture production was disproportionately appropriated by a small number of large properties, which displaced small rural owners and workers from the agricultural sector.

My main findings are robust to a series of deviations from the baseline framework. First, I use a series of different definitions for my exposure measure and find that the general conclusions remain unaltered. My main estimates also remain statistically significant when I correct standard errors to account for spatial correlation and correlation across the exposure shares. Finally, my results are robust to using microregions as a larger unit of observation. I then conclude that the 2000s commodities boom resulted in a structural transformation process. The use of capital inputs and rising land inequality increased in agriculture and labor was reallocated away from the agriculture sector and into manufacturing, spurring industrial growth.

**Related Literature.** This paper fits into different areas of the economics literature. First, it relates to research on the impacts of trade on structural transformation, includ-

ing access to fertilizers (McArthur and McCord, 2017), the effect of historical trade shock across regions within a same country (Fajgelbaum and Redding, 2018), and modernization of the agricultural sector (Farrokhi and Pellegrina, 2021). I contribute to this strand of the literature by exploring the relationship between a commodity price boom and agricultural modernization in modern local economies and by looking at the changes in input use and land inequality in the farms as potential and previously unexplored mechanisms related to agricultural modernization.

My work is also related to the literature that explores the effects of agricultural productivity on structural change in open economies (Matsuyama, 1992). Within this literature, several scholars have emphasized the relative importance of the comparative advantage effect, that draws resources into agriculture, versus the push effect.<sup>1</sup> Empirically, our setting is closely related to that of Bustos et al. (2016) and Bustos et al. (2020a) that show how the adoption of new agriculture technologies in soy and maize production can affect structural change in different directions depending on the factor-bias of agricultural technical change.<sup>2</sup> In another study, Bustos et al. (2020b) show that the previous reallocation of labor away from agriculture reinforced comparative advantage in the least skill-intensive manufacturing industries. Such effect happened because the displaced workers were relatively unskilled and had lower levels of human capital. While the series of works have deepened my knowledge about agricultural productivity and structural change, it still depends on two particular types of commodities.

There is also evidence that other types of technological changes in other agricultural crops imply different effects on trends of structural change. In a earlier work, Foster and Rosenzweig (2004) show that Indian villages with high rates of crop yield growth experienced lower industrial growth. Moscona (2018) shows that productivity growth associated with the Green Revolution in the last decades has been complementary to labor, increasing the employment share in agriculture both within and across countries, while also reducing urbanization and manufacturing employment. I contribute to this literature by providing new evidence about the relationship between the expansion of the agricultural sector, technology adoption, and structural transformation in a setting where a large set of commodities

---

<sup>1</sup>The labor push is the main drivers of structural transformation together with the pull effect. While the push effect is related to improvements in agricultural technology releasing labor away from agriculture, the pull effect considers improvements in industrial technology attracting labor out of agriculture (Alvarez-Cuadrado and Poschke, 2011).

<sup>2</sup>The authors explore the introduction of a new variety of genetically engineered (GE) soybean seed and of a second season in maize cultivation in Brazil. They argue that the GE soy seeds represent a labor-saving technical change in agriculture, while the new maize variety can be considered a land-augmenting technology. In the case of a labor-saving technology, labor and capital are reallocated away from agriculture and into manufacturing, while the opposite effect happens with the land-augmenting technology.

was affected by the boom, while also proposing new mechanisms related to input use and land inequality in the farms.

We also speak to the long-standing literature that studies the relationship between resource booms and development (Corden and Neary, 1982; Sachs and Warner, 1999, 2001; Gollin et al., 2016). In particular, my work is related to a recent strand that studies the effects of resource booms on local economies in the context of oil and gas discoveries (Allcott and Keniston, 2018; Cavalcanti et al., 2019) and coffee price shocks (Uribe-Castro, 2019). With a few exceptions, this literature has mostly focused on the extractive sector or specific crops and still lacks evidence on the widespread effects on structural transformation of a large boom across the whole agricultural sector. I contribute to this literature by exploring a boom across a wide basket of commodities that have heterogeneous patterns of production across the local economies.

## 2 Motivating Facts

The Brazilian economy relies heavily on agriculture and the country is among the largest producers in the world of coffee, sugarcane, soybean, maize, and beef. Furthermore, it is also characterized by regional variations in the degree of specialization in commodity output. The production of the agricultural crops, together with cattle raising, provide the basis for the large agribusiness industry in Brazil, which represents 22% of Brazil's GDP, a third of its employment, and almost 40% of its exports (PwC, 2013; FGV, 2015).

Products derived from agricultural production, like orange juice, ethanol, and paper also represent an important dimension of the large agribusiness industry in Brazil. In particular, the production of the derived products is characterized by high use of technology and agroindustry techniques. The agroindustry is, therefore, another important dimension in my analysis of the agricultural expansion, since part of the agricultural sector in Brazil can be characterized by economies of scale that are normally associated with the manufacturing sector. Furthermore, the agroindustry captures both farming production and the supply of farming inputs such as machinery and seeds.

Brazil has also one of the highest levels of land inequality in the world (Bauluz et al., 2020). According to the last Agricultural Census in 2017, less than 1% of all farms concentrate about half of the total rural area. The concentration of land remains surprisingly constant over time. Ever since the first Agricultural Census in 1920, the number of rural properties with more than 1000 hectares in area varied between 4% and 0.7% of the total number of agricultural establishments, but appropriated between 35% and 63% of the total area devoted to agriculture over the last 100 years. Figure 1 illustrates the differences in the

Land Gini for the Brazilian municipalities in 2017.

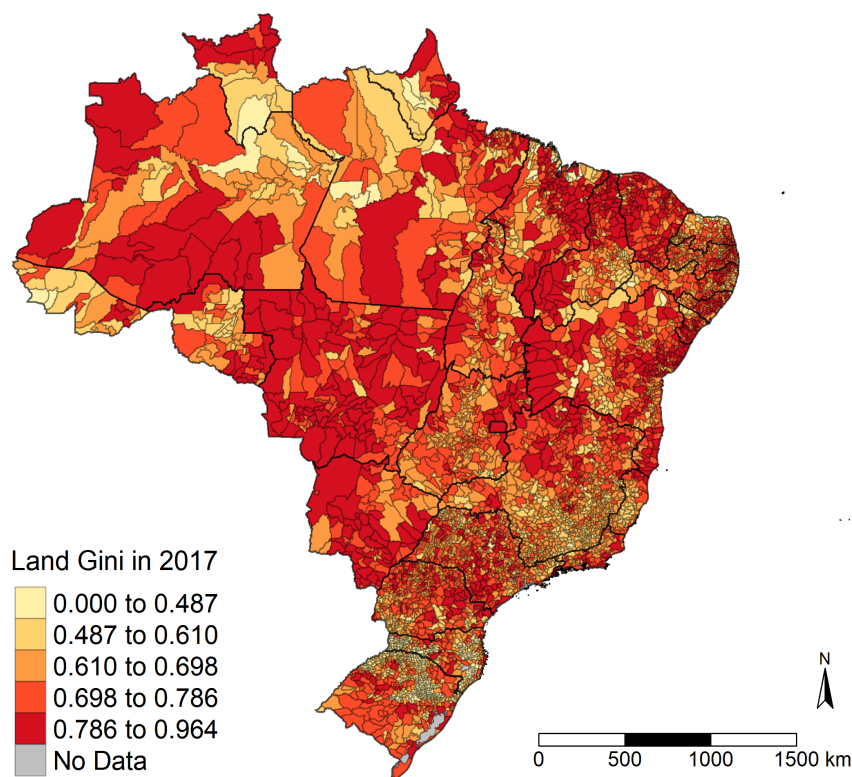

Figure 1: Land Inequality in Brazil

*Notes:* Author's calculations using the Brazilian Agricultural Census data from 2017. See [Appendix A.1](#) for variable definition and sources and [Appendix A.2](#) for details about the calculation of the Land Gini.

The characteristics of the Brazilian agricultural sector presented so far make the country a suitable setting to analyze the dynamics of structural change after the 2000s commodities boom. The last commodity supercycle started in 2000 and peaked in around 2011. Its magnitude is comparable to the other two historically observed supercycles that followed the Second Industrial Revolution and the aftermath of the Second World War ([Erten and Ocampo, 2013](#)). [Figure 2](#) illustrates how the prices of non-mineral agricultural commodities peaked very rapidly in about ten years after the 1990 decade when they were comparatively low.

Brazilian municipalities have also been experiencing a long process of structural transformation since the 1960s. [Figure 3](#) shows the evolution of employment shares in the main sectors of the Brazilian economy over time. Although the structural change has consolidated in the 1980 decade, we still observe a substantial reallocation of workers away from agricul-

Figure 2: 2000s Commodities Supercycle

*Notes:* Commodity Price Index in US\$ for agricultural products. Data from the World Bank’s Global Economic Monitor. See [Appendix A.1](#) for variable definition and sources.

ture in the last decades, especially between 2000 and 2010. In particular, the distribution of the employment shares differs substantially when analyzed at the municipality level.

The facts discussed above call for a careful examination of the differential trends of local development in the municipalities. I, therefore, analyze how the commodity price boom affected both the structure of the agriculture sector in terms of modernization and the regional development of the Brazilian economy.

### 3 Data

To construct my shift-share measure of exposure to the 2000s commodities supercycle, I obtain information on the local municipalities production of agricultural crops from the Instituto Brasileiro de Geografia e Estatística (IBGE). More specifically, I use the Produção Agrícola Municipal (PAM), which is held annually at the municipality level and has information on a set of variables such as planted area, quantities, and production values for a large set of crops produced in Brazil.

To obtain beef quantities, I use the Pesquisa da Pecuária Municipal (PPM), which is similar to the PAM and accounts for the creation of livestock in Brazil. The only drawback is that the PPM reports the number of cattle heads, not the actual weight of beef produced. To overcome such problem, I multiply the total number of livestock in each municipality by

Figure 3: Employment Shares Across Sectors in Brazil

*Notes:* Author's calculations from IPUMS International microdata for Brazilian Population Censuses. See [Appendix A.1](#) for variable definition and sources.

0.23, which is the average total carcass weight at slaughter in metric tons, to obtain a proxy for the production of beef in each municipality.<sup>3</sup>

I use data from the FAO-GAEZ project to obtain potential yields for each crop in my sample. The database consists of maximum attainable yields for multiple crops (in tons per hectare per year), which are considered as soil- and climate-based potential yields or productivity (total production capacity) measures. The crop-specific data relies purely on exogenous geo-climatic features, such as local soil and weather characteristics, which are then incorporated into a model that predicts the maximum attainable yields for each crop in a given area under different choices of water supply methods and input levels of technology use. The dataset is reported on a grid cell level, with each grid representing a 5-arc-minute resolution. At the 5-arc-minute level, there are around 255,680 grid cells in Brazil, representing around 11% of all grid cells on earth excluding bodies of water and ice shelves ([Costinot et al., 2016](#)). The area of the cells ranges from 8,586 hectares at the equatorial level to 6,031 hectares at the southern-most location in Brazil.

I aggregate the potential yields for each crop at the local level taking the mean value

<sup>3</sup>The average total carcass weight at slaughter in Brazil comes from the Pesquisa Trimestral do Abate de Animais from IBGE.

of each grid cell that falls within the border of each municipality and match all the crops present in the FAO-GAEZ with the previously obtained from the PAM/PPM dataset. I use data for rain-fed conditions under intermediate input technology—defined as a system in which “production is based on improved varieties, on manual labor with hand tools and/or animal traction and some mechanization”.<sup>4</sup> As a robustness check, I analyze the sensitivity of my results to using the high inputs.<sup>5</sup> With both PAM/PPM and FAO-GAEZ, I can then construct my “share” measure, consisting of the total production of crops in each municipality averaged over the 5 years preceding the start of my analysis.<sup>6</sup>

For the “shock” part of the exposure measure, I use the international commodity prices from the Global Economic Monitor (GEM) Commodities database prepared by the World Bank, which contains monthly information over an extended period on the price of several commodities that are traded in the international markets. I then average the prices over the twelve months within each year to obtain yearly values and standardized each price to US dollars per ton.<sup>7</sup> In some cases, there may be a single price that matches multiple crops in the quantities dataset, so I consolidate the shift-share measure by matching each possible crop to its broad international price, leaving space to more than one commodity being assigned to a single price<sup>8</sup>, while dropping the cases in which I cannot establish a match at all.

For the main outcomes and controls, I use data from the Brazilian Population Census, the Agricultural Census, and IPEADATA. Both agricultural and population censuses are released at intervals of ten years by IBGE. I obtain data from the last three rounds of the censuses (1996, 2006, and 2017 for agricultural and 1991, 2000, and 2010 for population). The agricultural census variables of interest are: the total number and area of farms,<sup>9</sup> area planted with genetically modified seeds, number of tractors and machines employed in the farms, output value in the agroindustry, number of workers, and total output of farms. The population census variables are: total employment, employment shares, and wages in agriculture, manufacturing, and services.

---

<sup>4</sup>For more details about the documentation of the FAO-GAEZ project, see [Appendix A.1](#) and [IIASA/FAO \(2012\)](#).

<sup>5</sup>Defined as being mainly market-oriented and where “production is based on improved high yielding varieties, is fully mechanized with low labor intensity and uses optimum applications of nutrients and chemical pest, disease and weed control”.

<sup>6</sup>In the case of cattle, I use potential yields for pasture as a proxy livestock productivity. Since extensive livestock creation composes the majority of the Brazilian production, the presence of pastures is still fundamental for cattle raising. I, therefore, assume that potential yields for pastures are a good proxy for cattle breeding productivity in my scenario.

<sup>7</sup>Throughout the paper, all variables representing monetary values were deflated to 2010 prices using the CPI inflation index for US dollars and the IPCA index for Brazilian Reais.

<sup>8</sup>For example, yerba mate and indiantea were both matched with the tea price.

<sup>9</sup>The two variables are reported into different intervals of area measured in hectares. I use the information to calculate the Land Gini in each municipality as described in [Appendix A.2](#).

From the population census, I also obtain start-of-period controls, such as income per capita, the share of rural population, illiteracy rate, and population density. From IPEA-DATA, I obtain additional geo-climatic and socio-economic characteristics such as sectoral and total GDP, latitude, longitude, municipality area, and rural and urban population. I also use historical population census microdata from IPUMS (Min, 2019) in my auxiliary analysis (to construct Figure 3, for example).

Finally, I use the Relação Anual de Informações Sociais (RAIS) to obtain disaggregated employment across different industries and alternative measures on total sectoral employment and employment shares in my analysis. RAIS is a yearly administrative database from the Brazilian Ministry of Labor (MTE), which provides matched employer-employee data at the individual level on the universe of formal sector employees. In my analysis, I aggregate the individual level data at the municipality level. Table 1 reports summary statistics for my main variables of interest and illustrates the evolution and difference in their values between the census years at the municipality level.

## 4 Empirical Strategy

The first part of the empirical analysis is to construct a shift-share (Bartik) measure to estimate the effects of the commodity price shocks on the local reallocation of production factors across the main sectors of the economy. I do so by interacting local agricultural endowment shares with the movements in global commodities prices. International prices are likely to be exogenous to local economic conditions, but local crop quantities are most likely not. Therefore, to obtain shares that are also exogenous, I combine the FAO-GAEZ potential yields with observed crop production patterns in the municipalities.

My framework extends the settings in Dube and Vargas (2013) and Bernstein et al. (2018) by constructing exogenous agricultural shares. Following Fiszbein (2019), I construct predicted agricultural shares for each municipality by incorporating the FAO-GAEZ crop-specific attainable yields into a fractional multinomial logit (FML) model. The framework is specified as a system of equations in which the outcome variables  $Q_{ki}$  are the observed shares of each agricultural product  $k$  in total agricultural output in municipality  $i$ , and the regressors are the crop-specific potential yields vector  $A_i$  measured in tons per hectare per year.

In my baseline specification, I use the average local crop  $k$  endowment share in municipalities over the period 1995-1999 ( $Q_{ki,99}$ ) to capture the pre-period exposure to the commodity boom that started in 2000.<sup>10</sup> The idea behind this is to create a proxy for local crop en-

---

<sup>10</sup>Later, I perform robustness checks using the mean crop production over 2000-2010.

Notes: See [Appendix A.1](#) for each variable definition and sources.

dowments shares that depends only on the FAO-GAEZ soil- and climate-based productivity measures, and therefore can be considered exogenous to local economic conditions. The functional form of the model is given by:

$$\hat{Q}_{ki} = E[Q_{ki,99}|A_i] = \frac{e^{\beta_k A_i}}{1 + \sum_{j=1}^{K-1} e^{\beta_j A_i}}. \quad (1)$$

By construction,  $\sum_{i=1}^I \hat{Q}_{ki} = 1$ , i.e, the predicted shares for each municipality add up to 1. The parameters are estimated by quasi-maximum-likelihood. We can motivate the FML framework by considering a simple model of optimal crop choice, as discussed in [Fiszbein \(2019\)](#). Assume, for instance, that farms are price-takers and choose to maximize profits. The profits obtained when choosing crop  $k$  for for a unit of farm resources  $l$  are given by the

the following equation:

$$\pi_{kl} = \beta'_i A_k + \epsilon_{kl} \quad (2)$$

where  $\pi_{kl}$  is the profit value for each choice of crop type and farm resource and  $\epsilon_{kl}$  is an error term. Then, the estimated parameters reflect the price and cost differentials among agricultural products, as well as any other factors that affect profits for different crops. If the error term is assumed to be *iid* with type I extreme value distribution, then choice  $k$  is optimal (i.e.  $\pi_{kl} \geq \pi_{k'l}$  for all  $k'$ ) with probability  $\frac{e^{\beta_k A_l}}{1 + \sum_{j=1}^{K-1} e^{\beta_j A_l}}$ .<sup>11</sup>

The next step is to interact the predicted shares with the international prices for each commodity. Let  $P_{kt}$  be the international price of crop  $k$  in year  $t$ . Since a municipality can be considered a small open economy, I assume that it cannot influence, in a significant manner, the yearly movements in international commodity prices. Therefore, the price variations can be considered exogenous to local outcomes related to the structure of the economy. My measure is then given by an annual Commodity Exposure (CE) measure for municipality  $i$  in year  $t$ :

$$CE_{it} = \sum_k \hat{Q}_{ki} \cdot \log P_{kt} \quad (3)$$

I draw from the recent advances in the shift-share literature to guarantee that the identification assumption of the empirical design holds. In particular, my approach follows closely the assumptions in [Borusyak et al. \(2018\)](#), where identification is achieved via exogeneity of the shocks.<sup>12</sup> My identification strategy consist of a special reduced-form case of their general shift-share instrumental variable analysis. I also apply the logarithmic transformation in the prices, and not in the whole measure, to avoid omitted variable bias as discussed in [Borusyak and Hull \(2020\)](#).

[Figure 4](#) shows the differential exposure of each municipality to the commodity supercycle. I plot the exposure measure constructed both with and without livestock production to give a dimension of strict farming agriculture and livestock production. I show in [Section 7](#) that my results do not change if I exclude cattle from the measure. [Figure 5](#) shows the distribution of the values for the CE measure for both years of my analysis. The values are reasonably well distributed, giving us a large sample of exposed vs non-exposed municipalities. [Figure 6](#) shows the change in the measure between 2000 and 2010.<sup>13</sup>

<sup>11</sup>[Figure B3](#) shows that the predicted shares are indeed good predictors for actual (observed) shares for all crops in the sample.

<sup>12</sup>For a further discussion about the shift-share literature and different complementary frameworks—where identification is achieved via exogeneity of the shares—see [Goldsmith-Pinkham et al. \(2020\)](#).

<sup>13</sup>The predicted measure is also a good predictor of the actual measure (constructed with the observable

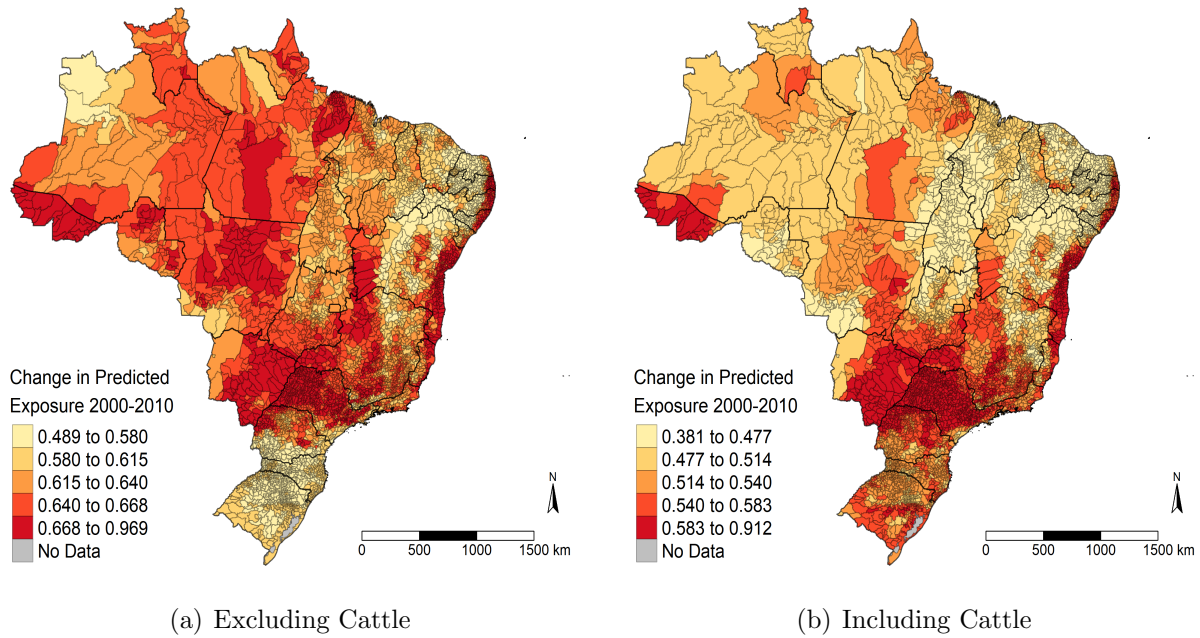

Figure 4: Exposure to the Commodity Shock

*Notes:* The maps display the spatial distribution of the change in the Commodity Exposure measure between 2000 and 2010, as defined in [Equation 3](#). Figure (a) displays the measure without the shares for cattle. Figure (b) displays the baseline measure that includes livestock production. See [Appendix A.1](#) for variable definition and sources.

The exposure measure also predicts the agricultural frontier expansion that happened after 2000 in Brazil. Recall that for my baseline measure I am using pre-period crop productions combined with crop-specific attainable yields from FAO-GAEZ, which do not depend on any contemporaneous pattern of agricultural production. The measure, therefore, captures how the current agricultural frontier benefited from the commodities boom. Consider, for example, the Central-West portion of Brazil and the areas close to the Amazon Forest frontier, which are highly productive agricultural areas today and were also greatly exposed to the shock according to the exposure measure ([Figure 4](#)).<sup>14</sup>

The last step is to estimate the main equation for the analysis, which allows to explore the effects of the commodities shocks on outcomes related to structural change in each

---

crop shares). [Figure B2](#) displays the scatter plot between the two measure values for all municipalities.

<sup>14</sup>The recent expansion of the agricultural frontier also generated important concerns about the possible negative environmental effects associated with the commodity boom. For a discussion, see [Assunção and Bragança \(2015\)](#) and [Bragança \(2018\)](#).

Figure 5: Histogram of the Commodity Exposure Measure

*Notes:* The figure displays the histogram for the Commodity Exposure measure as defined in [Equation 3](#) for the years 2000 and 2010 together. See [Appendix A.1](#) for variable definition and sources.

municipality. Formally, I estimate the following equation:

$$y_{it} = \beta CE_{it} + \alpha_i + \gamma_t + \delta X_{it} + u_{it} \quad (4)$$

where  $y_{it}$  is the outcome of interest that varies across municipalities  $i$  and time  $t$ ;  $CE_{it}$  is the Commodity Exposure measure as defined in [Equation 3](#);  $\alpha_i$  are municipality fixed effects and  $\gamma_t$  are time fixed effects;  $X_{it}$  is a vector of municipality control variables;  $u_{it}$  is an error term. My identification assumption relies on the exogeneity of the CE measure in the following way:

$$\mathbb{E}[u_{it} | CE_{it}, X_{i,t}, \alpha_i, \gamma_t] = 0. \quad (5)$$

Since I constructed it using a shift-share approach, I would only need either the shares or the shocks to be exogenous in relation to the outcomes, as discussed in the approaches of [Goldsmith-Pinkham et al. \(2020\)](#) and [Borusyak et al. \(2018\)](#). Nevertheless, I argued that both the shares and shocks in the exposure measure can be considered exogenous and, therefore, that the identification assumption holds.

Figure 6: Histogram of the Change in the Commodity Exposure Measure between 2000-2010

*Notes:* The figure displays the histogram for the Commodity Exposure measure as defined in [Equation 3](#) for the difference in the values between 2000 and 2010. See [Appendix A.1](#) for variable definition and sources.

In the case of sectoral employment share outcomes, my period of interest spans the ten years between the last two population censuses, which took place in 2000 and 2010. Similarly, for the agricultural censuses outcomes, I also have data on an interval of about ten years between the last two rounds (2006 and 2017). I thus estimate the first-difference version of [Equation 4](#):

$$\Delta y_i = \beta \Delta CE_i + \delta' X_{i,1991} + \Delta u_i \quad (6)$$

where the outcome of interest  $\Delta y_i$  is the change in outcome variables between the last two census years and  $\Delta CE_i$  is the change in the value of the exposure measure between 2000 and 2010.

I include controls for observable characteristics in the population census of 1991 to control for differential trends across municipalities with heterogeneous initial characteristics. In my specifications, I first add the share of rural population in 1991 and then extend the set of controls to also include population density, income per capita, illiteracy rates, and region fixed effect in the vector of controls.<sup>15</sup> The addition of such controls is important

---

<sup>15</sup>Region fixed effects include dummies variables for the five macroregions of Brazil: North, Northeast,

because it can be the case that municipalities with heterogeneous initial levels of development experiences different growth paths and then my estimates could be capturing differential structural transformation trends across municipalities.<sup>16</sup> Table 2 displays the average values of the main observable characteristics in 1991 for municipalities that ranked below and above the median change in the exposure measure ( $\Delta CE$ ).<sup>17</sup>

Note that I do not add any geo-climatic control to my main specification. If I controlled for any characteristic that was used to construct the FAO-GAEZ potential yields, the variable would act as a bad control in my regressions. The potential yields data already incorporate climate and soil characteristics, such as rainfall, temperature, wind speed, terrain slope, and soil types, and controlling for them would, therefore, bias my estimates.<sup>18</sup> In Section 7.2 I perform a robustness check that adds controls for other pre-period socioeconomic characteristics; geographic characteristics not incorporated in the FAO-GAEZ potential yields; and crop-specific controls.

## 5 Main Results

Now, I show how the commodity boom affected the profitability and growth of the major sectors in the Brazilian economy. In every table, the first column (1) displays the coefficients for the regression without any controls. In the subsequent columns (2) to (4), I account for different specifications that sequentially expand the baseline set of pre-period socio-economic controls to include region fixed effects, the share of rural population, illiteracy rate, log income per capita, and log population density.

Table 3 reports the estimates of the coefficient on the commodity shock exposure measure in regressions for total sectoral GDP across agriculture, manufacturing, and services. The estimates in column (4), my preferred specification, imply that the commodity boom greatly benefited the agriculture sector by increasing its GDP. I also observe a first evidence on the existence of a spillover effect of the commodity shock on other sectors of the economy. The magnitudes of the coefficients imply that if a municipality experienced an increase in the CE measure equivalent to a 1 standard deviation (0.064) from the average exposure to the commodity shock, Agricultural GDP per capita would increase by about 16.5 log points (18%). Similarly, I would also observe an increase of 0.7-2.1 log points (0.7-2.2%) in

---

Central-West, Southeast, and South.

<sup>16</sup>Take, for example, the state of São Paulo in the southeast region of Brazil which is one of the regions that benefited the most from the shock (as shown in Figure 4) and also one of the most developed regions in the country.

<sup>17</sup>Figure B1 in Appendix B complements the analysis by comparing the change in employment shares between 2000 and 2010 between the same municipalities that ranked above and below the exposure measure.

<sup>18</sup>See Cinelli et al. (2020) for a discussion about bad controls.

Table 2: Comparing Municipalities Below and Above the Median Exposure to the Commodity Shock

	Below $\Delta$ CE Median	Above $\Delta$ CE Median	Difference
Agricultural Employment Share	0.570	0.430	−0.140 (0.006)
Manufacturing Employment Share	0.085	0.130	0.044 (0.003)
Share Rural Population	0.611	0.410	−0.201 (0.007)
Log Income per Capita	4.993	5.571	0.578 (0.014)
Log Population Density	2.768	3.360	0.591 (0.037)
Illiteracy Rate	0.385	0.238	−0.148 (0.004)
Observations	2,738	2,737	

*Notes:* See [Appendix A.1](#) for variable definition and sources. The table presents the average values of observed characteristics of municipalities that rank below and above the median of the  $\Delta CE$  measure. All variables are from the population census of 1991. The third columns reports the difference between the second and first columns. Standard errors reported in parentheses.

Manufacturing GDP (columns (3)-(4)). The results for total GDP are positive and of about the same magnitude as the manufacturing sector. The results for the service sector GDP are negative and significant, implying a possible crowding out effect after the shock.

I now explore how labor reallocated after the commodity boom. [Table 4](#) reports the estimates of the coefficient on the commodity shock exposure measure in regressions for employment shares in agriculture, manufacturing, and services. According to my preferred specification, the estimates imply that a 1 standard deviation increase in the CE measure leads to a decrease of 0.8 percentage points (pp.) in the agricultural employment share. The estimate corresponds to about 10% of a standard deviation in the observed change of the agricultural employment share between 2000 and 2010 (8.1pp., see [Table 1](#)). In the case of manufacturing employment shares, the estimated coefficients in columns (4) indicate an increase of about 1pp. in manufacturing employment share, which corresponds to 18% of a standard deviation in the change between 2000 and 2010 (5.5pp.). I also do not observe any

the agricultural sector benefits heavily from the commodity shock. Since the exposure measure is constructed by multiplying prices by quantities—while also considering differentials in crop-specific agricultural productivity across locations—my results reflect how the commodity boom resulted in a significant increase in agricultural GDP. But most important than that, the boom generated a reallocation of labor away from agriculture, a result that might appear unintuitive at first.

I discuss the results in light of the recent literature that explores the localized effects of resource booms and the expansion of the agricultural sector. [Bustos et al. \(2016\)](#) finds that the adoption of genetically engineered (GE) soybeans across municipalities resulted

in a decrease of employment share in agriculture of about 24% of a standard deviation, with an increase in employment share in manufacturing of 31% of a standard deviation. Since the GE soy is characterized as a labor-saving technology, their estimates also imply that a 1% increase in agricultural labor productivity corresponds to a 0.157pp. increase in manufacturing employment share. While my estimates are slightly lower than theirs, I also find the same sign directions after the commodity price boom.

At a first moment, the reallocation of workers away from agriculture may not be expected since I am analyzing a large set of internationally traded commodities and holding crop-specific technological change constant. Moreover, many of the commodities in my sample are characterized by their labor-intensity in production and, therefore, differ fundamentally from the main hypothesis of [Bustos et al. \(2016\)](#). In their paper, they also look at the technical change in maize, which is found to be land-augmenting. The authors then find an opposite effect to that of the GE soy, with the expansion of maize being associated with an increase in the labor share of agriculture.<sup>20</sup> It could well be the case that, after the commodities boom, the agricultural sector expands its comparative advantage and draws labor in. My results imply, however, that such events did not happen, or at least were small in magnitude. My main hypothesis for the mechanism that led to the observed effect is discussed in [Section 6](#) and is related to fundamental changes in the use of capital and land in the agricultural sector.

In [Table 5](#), I explore how the commodity super-cycle impacted urbanization and wages across the same sectors. A 1 standard deviation increase in the exposure measure led to an increase of 0.2pp. in urbanization, which corresponds to 3% of a standard deviation of the change between 2000 and 2010. Analyzing the wages outcomes, my estimates imply that a 1 standard deviation in CE is associated with an increase of about 3% in wage in the agricultural sector and an increase of 4% in services. For wages in manufacturing, I observe the opposite effect, with a negative effect of 2%. Again, my results for the manufacturing sector are similar to that of [Bustos et al. \(2016\)](#) for the adoption of GE soy.

My results are also in line with the model and cross-country evidence in [Gollin et al. \(2016\)](#). The expansion of the agricultural sector associated with the commodity boom generated a positive urbanization effect, as predicted by their model. Although I do not observe localized effects on employment shares in the service sector, the rise in urbanization and employment share in manufacturing corroborate the “production cities” view. Moreover, my results also show that the commodity boom worked as a labor-push factor in agriculture.

---

<sup>20</sup>As already discussed in [Section 1](#), we still have few evidence on the effects of agricultural technical change on structural transformation, which also appear to be context-specific ([Gollin et al., 2018](#); [Moscona, 2018](#)).

*Notes:* See [Appendix A.1](#) for variable definition and sources. The table presents estimates of [Equation 6](#). The dependent variable is the 2000-2010 change in the listed outcomes. Column (1) reports the estimates without any control. Columns (2)-(4) extend the set of controls by including the share of population living in the rural area; region fixed effect for the 5 macroregions of Brazil; log income per capita; log population density; and illiteracy rate. All municipalities controls are from the population census of 1991. The means and standard deviations (in parentheses) of the dependent variables in panels A, B, C and D are 0.052 (0.063), 0.222 (0.393), 0.255 (0.560), and -0.300 (0.422). [Table C3](#) reports the coefficient for all the controls in the regression. Robust standard errors reported in parentheses. \*\*\* Significant at the 1% level; \*\* Significant at the 5% level; \* Significant at the 10% level.

I now turn my attention to the possible heterogeneous effects of the commodity boom on the manufacturing sector. Since I observed a positive relationship between the shock and the employment share in manufacturing, I extend my analysis to test the hypothesis if the reallocation of labor was directed at particular types of industries. To do so, I use the RAIS

dataset to divide the manufacturing sector into industries that are more linked to agriculture and consider them as being part of the agroindustry. The subsectors are related to food processing, beverage production, wood processing, and clothing. The other subsectors—which I label as heavy industry—are composed of chemical industries, electronics, pharmaceutical industry, metallurgy, machinery, and automotive industry.<sup>21</sup>

One possible drawback in my analysis is the fact that RAIS only covers formal jobs, which do not fully represent the highly informalized Brazilian labor market. The manufacturing sector, nevertheless, relies intensely on workers with formal labor contracts—which is not the case in agriculture and services—and, therefore, I assume that the RAIS data approximates reasonably well the employment share inside the whole manufacturing sector. In [Table 6](#) I show with the RAIS data that the commodity boom is associated with an increase in the manufacturing employment share of about the same magnitude that I have previously obtained with the population census data.

I also obtain the output value in agroindustry from the Agricultural Census to further explore how the subsector was impacted. My estimates imply that the production value of the agroindustry increases. After controlling for region fixed effects, the result loses significance and magnitude, but remains positive. The analysis of the employment shares outcomes shows that the reallocation of labor away from agriculture and into manufacturing appears to be equally distributed across the two subsectors that I have defined previously. A 1 standard deviation increase in the CE measure led to an increase of about 0.4pp. in agroindustry and 0.45pp. in the heavy industry.

My results imply that the resource boom associated with the commodity supercycle generated an important reallocation of labor away from agriculture and into manufacturing and, more importantly, the expansion of the manufacturing sector is equally distributed between the agroindustry more specialized transformation industries. Such effect could imply that the structure of the economy has changed to a higher sustained growth path, if it is assumed that the manufacturing sector is associated with higher productivity and spillover effects, like learning-by-doing as in [Matsuyama \(1992\)](#) model. The scenario of an increase in the long-term growth of the economy is, however, unlikely to occur in my setting. My analysis abstains from human capital considerations, which is a key dimension to take into consideration. Following their early work, [Bustos et al. \(2020b\)](#) show that the work reallocated into manufacturing after the adoption of the GE soy was relatively unskilled, which reinforced comparative advantage in the least skill-intensive manufacturing industries and slowed down local aggregate manufacturing productivity growth. Their effect is likely to be present in my analysis since agricultural labor in the Brazilian economy is characterized by low levels

---

<sup>21</sup>See [Appendix A](#) for a detailed definition of the sectors and subsectors.

of human capital accumulation.

## 6 Mechanisms

I now turn to my analysis of possible channels and mechanisms that might be driving the reallocation of workers away from agriculture and into manufacturing, while also increasing the manufacturing GDP and the wages in agriculture. My main hypothesis is based on exploring how the structure of the agriculture sector changed after the shock. I first look at the hypothesis that the commodity boom changed the use of inputs in the agriculture sector towards a more intensive use of capital in the farms. I also analyze if the commodity boom increased inequality in land ownership, increasing the land appropriated by larger farms and possibly displacing small owners from agriculture.

### 6.1 Use of Land, Capital Inputs, and Agricultural Productivity

In [Table 7](#) I explore how the commodity boom impacted the use of the other two fundamental inputs used in agriculture: land and capital. My main hypothesis in the present section is that changes in input use worked as a potential margin of adjustment to the commodity price boom. My first variable of interest is the log of total farmland that measures the expansion of land use in agricultural production. To analyze the capital adoption in farms I look at the intensity of machine use<sup>22</sup> and the share of agricultural land planted with genetically engineered (GE) seeds in each municipality. My estimates in column (4) imply that an increase of 1 standard deviation in the CE measure is associated with an increase in 4.5% in machine intensity and an increase of about 1.2pp. in the share of land harvested with GE seeds. The coefficients for total farmland loses significance as I control for region fixed effects and baseline controls.

Together with my main results from the previous section, I again interpret my findings as pointing to a relevant structural transformation effect after the commodity boom. In particular, the labor that was reallocated away from agriculture and into the manufacturing sector might have been substituted by agricultural machines as my results show.<sup>23</sup> Moreover, the increased use of GE seeds can also explain the displacement of agricultural workers. During the last two decades, GE seeds have been extensively adopted throughout Brazil. One of the main characteristics of GE seeds is that they are resistant to herbicides and facilitate the use of no-tillage planting techniques ([Bustos et al., 2016](#)). Therefore, one would expect that an increase in the use of GE seeds leads to a decrease in the number of

---

<sup>22</sup>Defined as the total number of tractors, planters, and harvesters in each municipality divided by the total farmland

<sup>23</sup>There is also a possible linkage effect that could be at play, but which I do not explore in-depth. It relates to the increase of machine intensity together with an increase in the manufacturing sector related to machine production.

workers per hectare needed to produce a fixed amount of agricultural output.

The results about the absence of effects on total farmland might seem less intuitive at a first moment. Although one could expect an increase of land devoted to agricultural production in more exposed municipalities after the commodity boom, several factors might explain the lack of effect that I observe. I focus on a particular hypothesis that the landowners could have been inefficiently using their farmland and, after the shock, increased the efficiency of production without expanding their farmland devoted to agricultural production. If the hypothesis events are indeed happening, I should at least observe the farm productivity increasing.

*Notes:* See [Appendix A.1](#) for variable definition and sources. The table presents estimates of [Equation 6](#). The dependent variable is the 2006-2017 change in the listed outcomes. Column (1) reports the estimates without any control. Columns (2)-(4) extend the set of controls by including the share of population living in the rural area; region fixed effect for the 5 macroregions of Brazil; log income per capita; log population density; and illiteracy rate. All municipalities controls are from the population census of 1991. The means and standard deviations (in parentheses) of the dependent variables in panels A, B and C are -0.019 (0.471), 0.392 (0.830), and 0.060 (0.171). Robust standard errors reported in parentheses. \*\*\* Significant at the 1% level; \*\* Significant at the 5% level; \* Significant at the 10% level.

In [Table 8](#) I show that it appears to be the case. I measure farm productivity as the total output of agriculture divided by the total farmland in hectares. My results show that the commodity boom is positively associated with farm productivity. The results also represent an important mechanism that might be driving my main results regarding structural transformation. The evidence on farmland productivity corroborates the findings in [Section 5](#) about the commodity boom working as a labor-push factor in agriculture.

I also explore if labor productivity—measured as the log output of farms per worker—in the agricultural sector increased after the commodities boom. If I observed a positive and significant effect of the exposure to the commodity boom on labor productivity, it could mean that the effects of labor-saving vs land-augmenting technologies are missing from my analysis. The prevalence of one type of technological change over another might be important in explaining the structural transformation patterns I observe. I do not observe, however, any statistically significant effect in my preferred specification. Since the literature has well-documented evidence on the adoption of both types of agricultural technical change in Brazil during the period which I analyze, it could be the case that their overall effect over structural transformation eventually cancels out.

## 6.2 Inequality in Land Ownership

I now explore how the commodity boom impacted the reallocation of farmland and land inequality across municipalities and how they might have worked as an important mechanism in driving the structural change effects I documented in the previous sections. Land inequality has been more extensively studied in the broad growth literature, but it is often overlooked in the structural transformation literature. One of the main hypothesis linked to the study of land inequality is related to the works of [Engerman and Sokoloff \(1994\)](#) and [Galor et al. \(2009\)](#), which suggest that inequality in the distribution of landownership had adverse effects on the emergence of public schooling during the transition from an agricultural economy to an industrial one. The hypothesis has been extensively tested in historical settings, implying that land inequality indeed played an important role in respect to long term economic development ([Easterly, 2007](#); [Vollrath, 2007](#); [Cinnirella and Hornung, 2016](#); [Wigton-Jones, 2020](#)).

In my setting, the results regarding land inequality, institutions, and human capital are unlikely to have a significant effect, mainly because I am analyzing a modern economy that has already experienced a major industrialization and expansion of public education. Nevertheless, I still propose that land inequality might be playing an important role in the relationship between commodity booms and structural transformation, in particular via

Table 8: The Effect of the Commodity Shock on Agricultural Productivity

*Notes:* See [Appendix A.1](#) for variable definition and sources. The table presents estimates of [Equation 6](#). The dependent variable is the 2006-2017 change in the listed outcomes. Column (1) reports the estimates without any control. Columns (2)-(4) extend the set of controls by including the share of population living in the rural area; region fixed effect for the 5 macroregions of Brazil; log income per capita; log population density; and illiteracy rate. All municipalities controls are from the population census of 1991. The means and standard deviations (in parentheses) of the dependent variables in panels A and B are 0.103 (0.830), and 0.025 (0.850). Robust standard errors reported in parentheses. \*\*\* Significant at the 1% level; \*\* Significant at the 5% level; \* Significant at the 10% level.

productivity changes and displacement of small landowners.

The relation between land inequality and agricultural productivity has been studied in [Vollrath \(2007\)](#). In a cross-sectional study of countries, the author finds that the Gini coefficient for land holdings is negatively associated with productivity in farms. In my setting, land inequality could increase after the commodity price boom given the structure of the Brazilian agricultural sector and its high and persistent inequality in landholdings discussed in [Section 2](#). One could also expect that productivity decreases given the rise in land inequality, supporting Vollrath's findings. On the other hand, productivity could also be positively related to land inequality and agricultural modernization. Since commodities such as soy, tobacco, cotton, sugarcane, and cattle raising are associated with large and productive farms, it could be the case that, after the shock, both land inequality and farm productivity increase in Brazil.<sup>24</sup>

<sup>24</sup>Although smaller farms were usually associated with higher productivity in the empirical literature,

In [Table 9](#) I explore how the commodity boom affected the Land Gini by taking short and long differences. I choose to report both types of results because land inequality, as a particular form of wealth inequality, is very persistent and changes slowly over time. My results imply that an increase of 1 standard deviation in the exposure measure led to an increase of 0.004 points in the short difference Land Gini (between the 2006 and 2017 Agricultural Censuses) and an increase of about 0.007 points in the long difference (between 1995 and 2017). The two effects account for about 5% of a standard deviation in the observed change.

I complement the pieces of evidence by exploring in [Table 10](#) the number of farms with more than 1000 hectares and the area appropriated by them in each municipality. I choose such arbitrary cutoff of total area because it captures the average farm size of the top 1% of agricultural establishments with respect to area appropriation, as reported in the Agricultural Census and discussed in [Section 2](#). I find that an increase of 1 standard deviation in the exposure measure is associated with an increase of 0.42% in the area of the top 1% farms in the short difference. The coefficient associated with the long difference is not statistically significant, although higher in magnitude. Analyzing the number of farms with more than 1000 hectares, I find that an increase of 1 standard deviation in the CE measure leads to an increase of 2.1pp. in the short difference and an increase of 8pp. in the long difference.

Together with the evidence in [Table 8](#), it appears to be the case that both agricultural productivity and land inequality increased, supporting the view that farms associated with large and modern field crops increased their productivity after the commodity shock. Moreover, since I observe both the Land Gini and the area and number of top 1% farms increasing without the same happening with total farmland, I interpret the results as also supporting the view that the commodity shock impacted structural transformation via the displacement of small landowners and workers away from agriculture.

## 7 Robustness Checks

### 7.1 Alternative Standard Errors

[Figure 4](#) suggests that the Commodity Exposure measure is correlated across space. I then consider a series of possible specifications of alternative standard errors to account for spatial correlation. First, I cluster the standard errors at a higher unit of observation to allow

---

there is a recent divergence between the microeconomic and macroeconomic evidence. For a discussion, see [Sanchez et al. \(2019\)](#).

The dependent variable is the 2006-2017 or 1995-2017 change in the listed outcomes. Column (1) reports the estimates without any control. Columns (2)-(4) extend the set of controls by including the share of population living in the rural area; region fixed effect for the 5 macroregions of Brazil; log income per capita; log population density; and illiteracy rate. All municipalities controls are from the population census of 1991. The means and standard deviations (in parentheses) of the dependent variables in panels A and B are -0.018 (0.084), and -0.007 (0.100). Robust standard errors reported in parentheses. \*\*\* Significant at the 1% level; \*\* Significant at the 5% level; \* Significant at the 10% level.

the residuals to be correlated within geographical areas larger than a single municipality. To do so, I cluster at the microregion level, which roughly represents Brazilian local labor market regions ([Adão, 2015](#)). The approach accounts for residual auto-correlation and spatial spillovers across nearby municipalities with economic links. I also cluster at a even higher unit of observation, the mesoregion, defined by IBGE, which are larger than microregions but smaller than the five macroregions.<sup>25</sup> Second, I calculate standard errors that correct for spatial dependence using different distance cutoffs as suggested by [Conley \(1999\)](#).<sup>26</sup>

My shift-share design can also suffer from a particular problem of inference that leads to overrejection. Regression residuals can be correlated across regions with similar shares, independently of their geographic location, and the OLS true variability may then be under-

<sup>25</sup>In 2010, there were 558 microregions and 137 mesoregions in Brazil.

<sup>26</sup>I implement the Conley standard errors using *acreg* command created by [Colella et al. \(2019\)](#) in Stata.

Columns (2)-(4) extend the set of controls by including the share of population living in the rural area; region fixed effect for the 5 macroregions of Brazil; log income per capita; log population density; and illiteracy rate. All municipalities controls are from the population census of 1991. The means and standard deviations (in parentheses) of the dependent variables in panels A, B, C and D are -0.783 (3.522), -2.790 (4.573), 0.024 (0.530), and 0.030 (0.722). Robust standard errors reported in parentheses. \*\*\* Significant at the 1% level; \*\* Significant at the 5% level; \* Significant at the 10% level.

stated when using the usual clustering or heteroskedasticity-robust errors. I then apply the AKM and AKM0 corrections proposed by [Adao et al. \(2019\)](#) to account for the dependence between residuals generated by unobserved shift-share components.

[Tables 11, 12 and 13](#) report the alternative standard errors for my main results regarding the effects of the commodity boom on structural change, input use, and land inequality. I

report coefficients for my main specification (column (4) in the previous tables), as well as the coefficients for the main specification but without region fixed effects. I remove the region fixed effects because the *reg-ss* package developed by [Adao et al. \(2019\)](#) that implements the AKM and AKM0 corrections does not allow for fixed effects regressions.

The significance of my results remains the same in respect to employment shares and wages. Only the effects on urban population share appear to lose significance when I account for spatial correlation. The significance of the coefficients for input use also remain mostly the same, with only the coefficient for spatial correlation above 200km losing significance. The results for land inequality also remain statistically significant with the exception of the coefficient for the short difference in the Land Gini for the 400km cutoff.

## 7.2 Additional Controls

A potential concern regarding my analysis is that specific commodities, such as soy, meat, or sugarcane, are driving the results. Moreover, municipalities more exposed to the commodities boom can also have higher overall agricultural productivity or different labor force composition prior to the shock. My estimates could then be capturing specific specialization in commodity production or differential trends of structural transformation across locations. To address the differential trends, I report estimates of [Equation 6](#) including the following additional controls: share of women in the labor force in 1991; land productivity in 1995 (measured as the log value of output per total farmland); a dummy variable if a commodity represents individually more than 30% of a municipality’s total agricultural production; and a dummy variable if a group of commodities (meat, coffee, maize, soybean, and sugarcane) represents together more than 50% a municipality’s total agricultural production. I also add a control for altitude—which is an important geographical characteristic not incorporated in the FAO-GAEZ potential yields model—and other proxies for access to markets, such as distance to the federal capital; distance to the state capital; and state capital dummy.

[Tables C4](#) and [C5](#) report the coefficients for the main regressions with the full set of additional controls. The sign of estimated coefficients remains the same, while also remaining significant and of similar magnitude for the main outcomes (the only exception is the coefficient for urbanization). Overall, my results remain stable over the inclusion of a set of additional variables that controls for initial agricultural development, labor force composition, geographical characteristics, and prevalence of specific commodities.

### 7.3 Alternative Measures

I now consider alternative definitions for my Commodity Exposure Measure. Based on the continuous measure defined in [Equation 3](#), I construct dummy variables that equal one if the difference in the CE measure is in some given top or bottom percentile of its distribution. I could then interpret that a municipality is “treated” if the dummy variable equals one. For the percentile thresholds, I construct dummy variables for the top and bottom 10th and 25th percentiles, as well as for the values above and below the median of the distribution.

[Tables 14](#), [15](#) and [16](#) report the coefficients for my preferred specification on the main outcomes using the alternative measures. Overall, the results remain qualitatively the same, but the interpretation of the coefficients is different. Now, I am comparing the municipalities above or below an arbitrary threshold of the CE measure distribution with the rest of the municipalities. In respect to employment shares, the results show that if a municipality is the the top 10% or top 25% of the  $\Delta$  CE measure distribution, it experiences a decrease in employment share in agriculture of 2.1-2.4 pp. and an increase of 2.5-2.7pp. in employment share in manufacturing. The bottom dummies also corroborate my main findings. Being in the bottom distribution of the  $\Delta$  CE measure is associated with no effect on employment shares, urbanization, and wages. In some cases there are even opposite effects in comparison with the municipalities in the top of the distribution. The results on input use and land inequality also remain qualitatively the same except for the machine intensity variable.

I also perform robustness check regarding the definition of the Commodity Exposure measure constructed in [Equation 3](#). First, I use the mean commodity production in PAM for actual the supercycle period (2000-2010) to construct the shares in the FML model. Second, I exclude cattle shares from the baseline measure. Third, I use the FAO-GAEZ high inputs in the FML model. [Tables C6](#), [C7](#) and [C8](#) report the estimates for the three different definitions for the CE measure. The results remain consistent with the main estimates in both magnitude and significance.

### 7.4 Observations at a Large Aggregation Level

A potential issue in the empirical analysis performed so far is that some municipalities might be too small to capture flows between rural and urban areas, which are usually associated with agricultural and manufacturing labor. I then aggregate my municipality-level observations at the microregion level, which represents a larger unit of observation and, as discussed previously, also represents Brazilian local labor markets. [Tables C9](#), [C10](#) and [C11](#) report the baseline estimates at the microregion-level. The results have similar magnitude and are consistent with the estimates reported in [Section 5](#).

## 8 Conclusion

I showed that the 2000s commodity supercycle led to a significant structural change in Brazilian municipalities between 2000 and 2010. My identification strategy relied on constructing a shift-share measure by interacting climate- and soil-based measures of crop-specific potential yields with the international prices of commodities. The shift-share measure then reflects an exogenous variation of local exposure to the commodity shock by combining both the cross-sectional and time dimensions. I find that, after the boom, labor was reallocated away from agriculture and towards the manufacturing sector. The reallocation of labor was widespread and did not benefit any specific industrial sector. It also impacted formal and informal jobs in the manufacturing sector symmetrically. I explore the possible mechanisms that are driving the observed effect and find that substitution of labor by capital in the farms and increasing inequality among landowners are important and previously unexplored factors that might be driving the results. The mechanisms suggest an increase of large and mechanized farms, pointing to a relevant agricultural modernization process in the Brazilian economy after the agricultural boom.

I also interpret my results in terms of the impact of trade on structural transformation. My results show that the interaction between trade and agricultural productivity after the commodities boom resulted in a structural transformation process that relied heavily on the agricultural modernization of the farms. Taking into account the evidence presented in this paper together with that in [Bustos et al. \(2016\)](#), it appears that changes in the structure of the modern agricultural sector in Brazil—via exogenous prices variations or technological change—can indeed generate structural transformation and overcome the comparative advantage effect of drawing labor into agriculture.

Although deindustrialization and low trends of growth and productivity are salient features in the Brazilian economy during the last decades, my work provides evidence that the commodity boom is not one of the fundamental causes of such issues. I raise the hypothesis that the usual suspects, such as the overall quality of institutions and the accumulation and quality of human capital might be the key factor preventing the betterment of productivity and economic growth in the economy. I do not, however, test directly for the human capital hypothesis and leave it for future work.

# Appendix

## A Data

The present section contains a detailed description and the sources of the main variables used in the paper.

### A.1 Definitions and Sources

#### Variables for Constructing the Commodity Exposure Measure

**Observed shares of each crop ( $Q_{ki}, 99$ ):** Data on the observed shares of each crop between 1995 and 1999 is from the Produção Agrícola Municipal (PAM) and Pesquisa da Pecuária Municipal (PPM) and it is sourced from the IBGE online data repository SIDRA. I construct the variable by dividing the quantities of each crop in each municipality-year observation by the total quantity of all crops used in the sample for each observation. [Table A1](#) reports the number of municipalities producing each type of crop. Data for the quantities of seasonal and permanent crops in PAM is from Tabela 5457. Data for the number of cattle heads in PPM is from Tabela 3939.

**Crop-specific potential yields:** Data on potential yields comes from the Global Agro-Ecological Zones project v3.0 ([IIASA/FAO \(2012\)](#)), which is publicly available on their website.<sup>27</sup> The variable measures agricultural suitability as the maximum attainable yields for a crop in a certain geographical area and are reported in tons per hectare per year for each crop in each grid cell of 0.083x0.083 degrees. FAO uses information on climatic conditions—including precipitation, temperature, wind speed, sunshine hours and relative humidity—together with data on soil, topography and elevation to determine the maximum attainable yields. FAO’s data also enable us to choose different types of inputs and water supply conditions. I use data on intermediate levels of inputs/technology and rain-fed conditions, which better approximates my scenario.

The definition of each inputs/technology in the FAO-GAEZ dataset documentation is as follows. Low-level inputs/traditional management: "Under a low level of inputs (traditional management assumption), the farming system is largely subsistence based. Production is based on the use of traditional cultivars (if improved cultivars are used, they are treated in the same way as local cultivars), labor intensive techniques, and no application of nutrients, no use of chemicals for pest and disease control and minimum conservation mea-

---

<sup>27</sup><http://www.gaez.iiasa.ac.at/>.

Table A1: Agricultural Endowments  
Across Municipalities

	Number of Municipalities	
	2000	2010
Cattle	5471	5518
Maize	5329	5176
Rice	4071	3084
Banana	3795	3555
Orange	3634	3006
Sugarcane	3483	3695
Coffee	2008	1822
Soybean	1446	1800
Cotton	1272	411
Tobacco	958	892
Wheat	802	895
Yerba Mate	555	474
Sorghum	469	604
Cocoa	264	282
Barley	173	135

*Notes:* See [Appendix A.1](#) for variable definition and sources. The table presents the number of Brazilian municipalities that produce each of the crop in my analysis.

tures.” Intermediate-level inputs/advanced management: ”Under an intermediate level of input (improved management assumption), the farming system is partly market oriented. Production for subsistence plus commercial sale is a management objective. Production is based on improved varieties, on manual labor with hand tools and/or animal traction and some mechanization, is medium labor intensive, uses some fertilizer application and chemical pest disease and weed control, adequate fallows and some conservation measures.” High-level inputs/advanced management: ”Under the high input, advanced management assumption, the farming system is mainly market oriented. Commercial production is a management objective. Production is based on improved high yielding varieties, is fully mechanized with low labor intensity and uses optimum applications of nutrients and chemical pest, disease and weed control.”

**International commodity prices:** Data on international commodity price comes from the Global Economic Monitor (GEM) Commodities database published by the World Bank, which is publicly available on their website.

## Outcome Variables

**Total GDP per capita:** Data on Total Gross Domestic of Municipalities is from the *Produto Interno Bruto dos Municípios* series by IBGE. I use the values for 2000 and 2010 in my analysis. The values are reported in current values in Reais in the respective years. In order to deflate all 2000 values to 2010 Reais, I used the annual IPCA (Índice Nacional de Preços ao Consumidor Amplo). In order to obtain per capita values, I divide the real values by the total population in each municipality taken from the Population Census.

**Agricultural GDP per capita:** Data on Agricultural GDP per Capita is obtained in the same way as Total GDP per Capita

**Manufacturing GDP per capita:** Data on Agricultural GDP per Capita is constructed in the same way as Total and Agricultural GDP per Capita.

**Services GDP per capita:** Data on Agricultural GDP per Capita is constructed in the same way as Total, Agricultural and Manufacturing GDP per Capita.

**Employment share in agriculture:** Data on employment share in agriculture come from the Brazilian Population Censuses of 2000 and 2010. The variable is calculated as total number of people who reported working in the agricultural sector divided by the total number of people that reported being employed in any sector of the economy. Sector of employment is reported according to the first version of the CNAE-Domiciliar in both 2000 and 2010. The agricultural sector is defined as any sector with the codes ranging from 01 to 05, which encompasses the Sections A: Agriculture, Livestock, Silviculture and Forest Production and B: Fishing. Original data come at the individual level and I use the municipality-level aggregation provided by the Atlas do Desenvolvimento Humano no Brasil ([PNUD, 2020](#)).

**Employment share in manufacturing:** Data on employment share in manufacturing come from the Brazilian Population Censuses of 2000 and 2010. The variable is calculated and aggregated in the same way as employment share in agriculture. The manufacturing sector is defined as Sections C: Extractive Industries and D: Transformation Industries, with the codes ranging from 10 to 37.

**Employment share in services:** Data on employment share in services come from the Brazilian Population Censuses of 2000 and 2010. The variable is calculated and aggregated in the same way as employment share in agriculture and manufacturing. The service sector is defined as Sections G: Commerce; H: Transportation; I: Accommodation and Food; J: Information and Communication; K: Financial Activities; L: Real Estate; M: Professional,

Scientific and Technical Activities; N: Administrative Activities; O: Public administration, defense and social security; P: Education; Q: Health; R: Arts, Culture, Sport and Recreation; S: Other Services; T: Domestic Services, with the codes ranging from 45 to 97.

**Wages in agriculture:** Data on the wage in agriculture come from the Brazilian Population Censuses of 2000 and 2010. All wages are reported in current values in Reais in the respective years of the two Censuses. In order to deflate all 2000 values to 2010 Reais, I used the annual IPCA (Índice Nacional de Preços ao Consumidor Amplo).

**Wages in manufacturing:** Data on the wage in manufacturing come from the Brazilian Population Censuses of 2000 and 2010. The variable is constructed in the same way as the wages in agriculture.

**Wages in services:** Data on the wage in services come from the Brazilian Population Censuses of 2000 and 2010. The variable is constructed in the same way as the wages in agriculture and manufacturing.

**Urban population share:** Data on the urban population share come from the Brazilian Population Censuses of 2000 and 2010. The variable is constructed by dividing the total population living in urban areas with the total population in each municipality.

**Output in agroindustry:** Data on the output value in the agroindustry is from the Brazilian Agricultural Census of 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA.<sup>28</sup> Data of 2006 is from Tabela 4081 and of 2017 from Tabela 6960.

**Employment share in manufacturing - RAIS:** Data on alternative employment share in manufacturing come from the *Relação Anual de Informações Sociais* (RAIS) from the Brazilian Ministry of Labor.<sup>29</sup> The manufacturing sector is defined the same way as before, using Sections C: Extractive Industries and D: Transformation Industries from CNAE, with the codes ranging from 10 to 37.

**Employment share in agroindustry:** Data on employment share in agroindustry come from the *Relação Anual de Informações Sociais* (RAIS) from the Brazilian Ministry of Labor. The agroindustry sector is defined using codes 152 to 214, which include the processing of food; beverage production; manufacturing of textile products; clothing; wood and paper processing.

**Employment share in heavy industry:** Data on employment share in agroindustry come

---

<sup>28</sup>[www.sidra.org.br](http://www.sidra.org.br).

<sup>29</sup>As of 2020, the Ministry of Labor has been incorporated into the Ministry of Economy.

from the *Relação Anual de Informações Sociais* (RAIS) from the Brazilian Ministry of Labor. The heavy industry sector is defined using codes 24 to 37, which include the chemical industry; pharmaceuticals; metallurgy; machinery; electronics; automotive industry; furniture.

**Total farmland:** Data on the total farmland is from the Brazilian Agricultural Census of 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA. Data of 2006 is from Tabela 787 and of 2017 from Tabela 6878.

**Machine intensity:** Data on the machine intensity is from the Brazilian Agricultural Census of 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA. I construct the variable by obtaining the total number of tractors, seeders, planters, harvesters and fertilizers used in the agricultural establishments (farms) in each municipality. I then divide the total number of machines by the total farmland. Data of 2006 is from Tabela 860 (tractors) and Tabela 861 (other machines). Data of 2017 is from Tabela 6898 (tractors) and Tabela 6872 (other machines).

**Share of land with GE seeds:** Data on the share of land harvested with GE seeds is from the Brazilian Agricultural Census of 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA. Data of 2006 is from Tabela 824 and of 2017 from Tabela 6958.

**Farm productivity:** Data on farm productivity is from the Brazilian Agricultural Census of 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA. I construct the variable by dividing the total value of output in agricultural for each municipality by the total farmland. Data of 2006 for Total value of production in agriculture is from Tabelas: 1823 (value of production by seasonal crop), 1177/1178 (value of production by permanent crop), 818 (value of production by horticulture product), 815 (value of production by forestry product), 816 (value of production by vegetable extraction product), 782 (value of bovines), 937 (value of swines), 943 (value of poultry). Data for 2017 is from Tabelas: 6957 (value of production by seasonal crop), 6955 (value of production by permanent crop), 6953 (value of production by horticulture product), 6949 (value of production by vegetable extraction product), 6947 (value of production by forestry product), 6940 (value of poultry), 6927 (value of swines), 6910 (value of bovines).

**Output per worker:** Data on output per worker is from the Brazilian Agricultural Census of 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA. I construct the variable by dividing the total value of output in agricultural for each municipality by the number of workers in agriculture. Data for the number of workers in 2006 is from Tabela 956 and in 2017 from Tabela 6889.

**Land Gini:** Data on Land Gini is from the Brazilian Agricultural Census of 1995, 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA. I detail the construction of the variable in [Appendix A.2](#). I use data for the total area and number of farms in each municipality. Data for the area of agricultural establishments in 1995 is from Tabela 315, of 2006 is from Tabela 787 and of 2017 from Tabela 6878. Data for the number of farms in 1995 is from Tabela 312, of 2006 is from Tabela 860 and of 2017 from Tabela 6880.

**Area of farms  $\leq 1.000$  ha:** Data on the area of farms with more than 1.000 ha is from the Brazilian Agricultural Census of 1995, 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA. The data is from the same tables used in the Land Gini.

**Number of farms  $\leq 1.000$  ha:** Data on the number of farms with more than 1.000 ha is from the Brazilian Agricultural Census of 1995, 2006 and 2017 and it is sourced from the IBGE online data repository SIDRA. The data is from the same tables used in the Land Gini.

## Control Variables

**Share of rural population:** Data on the share of rural population come from Brazilian Population Censuses of 1991. The variable is constructed by dividing the total number of people that reported living in rural area with the total population in each municipality. Original data come at the individual level and I use the municipality-level aggregation provided by the Atlas do Desenvolvimento Humano no Brasil ([PNUD, 2020](#)).

**Illiteracy rate:** Data on the illiteracy come from Brazilian Population Censuses of 1991. The variable is calculated considering only people 10 years or older, as the total number of people who is able to read and write divided by the total number of people. Original data come at the individual level and I use the municipality-level aggregation provided by the Atlas do Desenvolvimento Humano no Brasil ([PNUD, 2020](#)).

**Income per capita:** Data on income per capita come from Brazilian Population Censuses of 1991. Income is defined for every person as the sum of income coming from all sources. Original data come at the individual level and I use the municipality-level aggregation provided by the Atlas do Desenvolvimento Humano no Brasil ([PNUD, 2020](#)).

**Population density:** Data on population density come from Brazilian Population Censuses of 1991 and IPEADATA. I construct the variable by dividing the total population of each municipality by its total area in square kilometers. Data of municipality area is from IPEADATA.

## Variables Used in Figures and Additional Results

**Employment shares from Figure 3:** Data on employment shares since 1960 in Brazil come from IPUMS International microdata for the Brazilian Population Census (Min, 2019). The dataset enables us to construct employment shares in the usual way, but also keeping the variables in each year harmonized throughout the different definitions of occupations in the Censuses using ISCO and SIC codes, which follow a similar structure than that of CNAE.

### A.2 Land Gini Calculation

The three rounds of the Agricultural Census (1995, 2006 and 2017) divide the area of rural properties into different intervals, reporting the total number and total area of properties across different bins of total area. I am then able to calculate the mean property size within each interval. I follow Nunn (2008) and use the Stata program *ineqdec0* written by Stephen P. Jenkins, to obtain the Gini coefficient as follows:

$$\text{Gini} = 1 + \left(\frac{1}{n}\right) - \frac{2 \sum_1^n (n - i + 1) a_i}{n \sum_i^n a_i}$$

where  $n$  is the number of farms,  $a_i$  is farm size in acres, and  $i$  denotes the rank in ascending order of  $a_i$ .

## B Additional Figures

Figure B1: Employment Shares (Mean and 1SD Error Bars)

*Notes:* The figures display the average employment shares, and their respective 1 standard error bars, in Brazilian municipalities that were ranked above and below the  $\Delta CE$  measure. Data are from the 2000 and 2010 Population Census. See [Appendix A.1](#) for variable definition and sources.

Figure B2: Actual and Predicted Exposure Measure

*Notes:* The figure displays the scatter plot of actual and predicted  $\Delta CE$  measure constructed in [Equation 3](#). Predicted shares are obtained from the FML model. The figure reports the coefficient, robust standard error, and t-statistic of the bivariate regression between the two variables. See [Appendix A.1](#) for variable definition and sources.

Figure B3: Actual and Predicted Agricultural Shares

*Notes:* The figures display the scatter plot of actual and predicted shares for all crops in the sample. The figure reports the coefficients, robust standard errors, and t-statistics of the bivariate regression between the two variables in each graph. Predicted shares are obtained from the FML model. See [Appendix A.1](#) for variable definition and sources.

## C Additional Results

Table C1: The Effect of the Commodity Shock on Employment Shares in the Formal Sector

	(1)	(2)	(3)	(4)
<b>Panel A.</b>	$\Delta$ Employment Share in Agriculture			
$\Delta$ CE	-0.355*** (0.033)	-0.353*** (0.040)	-0.176*** (0.052)	-0.195*** (0.056)
Adj. $R^2$	0.026	0.026	0.050	0.171
<b>Panel B.</b>	$\Delta$ Employment Share in Manufacturing			
$\Delta$ CE	0.135*** (0.029)	0.067** (0.032)	0.051 (0.039)	0.098** (0.045)
Adj. $R^2$	0.009	0.012	0.044	0.059
<b>Panel C.</b>	$\Delta$ Employment Share in Services			
$\Delta$ CE	0.222*** (0.043)	0.289*** (0.055)	0.155** (0.068)	0.128* (0.074)
Adj. $R^2$	0.012	0.013	0.052	0.062
Rural Share in 1991		✓	✓	✓
Region FE			✓	✓
Baseline Controls				✓
Observations	5,455	5,455	5,455	5,455

*Notes:* See [Appendix A.1](#) for variable definition and sources. The table presents estimates of [Equation 6](#). The dependent variable is the 2000-2010 change in the listed outcomes. Column (1) reports the estimates without any control. Columns (2)-(4) extend the set of controls by including the share of population living in the rural area; region fixed effect for the 5 macroregions of Brazil; log income per capita; log population density; and illiteracy rate. All municipalities controls are from the population census of 1991. The means and standard deviations (in parentheses) of the dependent variables in panels A, B, and C are -0.023 (0.125), 0.001 (0.117), and 0.021 (0.170). Robust standard errors reported in parentheses. \*\*\* Significant at the 1% level; \*\* Significant at the 5% level; \* Significant at the 10% level.

Table C2: The Effect of the Commodity Shock on Total Employment Across Sectors

	(1)	(2)	(3)	(4)
<b>Panel A.</b>	$\Delta$ Log Total Employment			
$\Delta$ CE	0.442*** (0.045)	0.155*** (0.048)	0.198*** (0.071)	0.107** (0.053)
Adj. $R^2$	0.016	0.060	0.157	0.124
<b>Panel B.</b>	$\Delta$ Log Total Employment in Agriculture			
$\Delta$ CE	-0.076 (0.073)	-0.267*** (0.076)	-0.215*** (0.083)	-0.279*** (0.084)
Adj. $R^2$	0.000	0.008	0.033	0.039
<b>Panel C.</b>	$\Delta$ Log Total Employment in Manufacturing			
$\Delta$ CE	2.238*** (0.144)	2.075*** (0.156)	1.562*** (0.167)	1.449*** (0.172)
